MEY NORGANING COMMUNICATION CONTRACTOR IN THE PROPERTY OF THE

cripitul neutalgia (ON) is a sare deu-Irological disorder characterized by severe episodes of lancinating painwithin the distribution of the greater and lesser nortipital netwes (16), ON attacks are comparable with those of trigominal or glossopharyngeal neuralgias, except that in case of ON, pain mostly involves occipital and partauricular areas with possible retro-orbital radiation and can be often bilateral (16, 17). In rare occasions, pain may radiate also to the side of the head or to the frontal region (11). Similar to other neuropathic pain syndromes, ON attacks can be provoked by palpating a trigger point, which in most cases identified as the occipital rotch (5). Trauma of the C2 root. during normal or excessive movements (e.g., whichash injury) of the head or by attitritic

changes of the atlautoaxial joint is thought to by the main cause of ON (21, 30). Sustained contraction or spasm of the posterior neek musides have also been implicated as a cause. of ON (32). However, very other, the offending agent (previous trauma, corvical spundy) losis, or ligamentess hypertrophy) cannot be essily identified, and for these patients, the cEnlogy of ON remains unknown (18). Therefore, neuropathic changes in greater or kesser. occipital nerve in these cases are considered idiopathic.

Various therapies have been tried in the rnamagement of intractable ON. These range from noninvasive, drug based therapies, such as different combinations of oral and topical analgesics, anticonvulsant, antidepressant, and even antiviral agents, to indumally invasive Exhibitions, such as trigger point injections with the mixture or local are sthetic and steroid (which may be both diagnostic and therapeuric), transculaneous electrical nervestimulation, and different nerve blocks, to highly investive, surgery-based therapies, such as misirolysis of the greater or lesser accipital nerve, intradural rhizotomy of the C2 mot, selective partial posterior rhizotomy of C1 to C3 roots, C2 ganglionerlamy, or C2 root decompression (3, 4, 7, 9, 13, 13, 16, 20, 22, 24, 29, 31, 38). Even acupuncture techniques and repeated injections of containing taxin type A have been fried with a variable rate of success (8, 19, 57, 40). Despite all efforts, none of these treatment options provides complete long-term relief of symptoms without causing significant side effects (22). With fine, the attacks of ON can become very sevent and intractable to above mentioned treatment modalities, which can significantly impair a patient's quality of life, disrepting normal daily activities.

Chronic incipital nerve stimulation (ONS) is another mudality for treatment of chronic excipital headache (39). It may provide good long-term relief from painful attacks of ON without virtually any significant side effects. The idea of pain inhibition by chronic nerve stimulation originated from the gate-control theory of pain, which was introduced by Melzack and Wall (25) almost 50 years ago, although some specific assumptions of this original hypothesis were not confirmed by subsequent investigations (26, 34, 36). The current understanding of possible neutronodulation mechanism with chronic electrical stimulation is based on the fact that the

electrical corrent applied during stimulation can directly block cell membrane depolarization and axonal conduction in afferent states, so the patient experiences light lingling sensation. instead of pain in areas innervated by stimulated nerves (14). In the past, repetitive electrical stimulation of human prripheral nerves was shown to produce excitation failure in C fibers, which are responsible for propagation of painful stimtdf (35). Altomotively, it was postulated that electrical stimulation of a peripheral nerve may block more distal nociceptive input by Inhibitory action at the dorsal horn, begin stem, or thalamus (6, 10, 23). However, the pathophysiological mechanism of pain relief with peripheral nerve stimulation (PNS) in patients with medically intractable ON still remains unclear because factual experimental or clinical data available in the literature on this subject are very limited. In this acticle, we present our experience with ON5 in 14 patients with chronic ON treated in the University of Illinois at Chicago Medical Center for the period from April 2002 to November 2004.

PATIENTS AND METHODS

Patient Demographics

We conducted a retrospective study of 14 patients freated with caronic ONS and upscated on by our team from April 2002 to November 2004 for intractable ON (Table 1) Original presiperative and postoperative clinic notes, operative reports, hospital charts, and direct patient follow-up during regular

clinic visits were used. All patients in this study were diagnosed with characte, intractable ON according to guidelines of the International Headache Society (12). They all presented at their initial visit to out chara with complaints of severe sharp stabbing pain in occipital and with or without radiation to other parts of the head, neck, or shoulder. The duration of pain attacks varied from several minutes to reverse days, and the frequency from several times per month to several times per day. Palpation of the excipital area or upper neck on the afforted side usually revealed move e tenderces and in most cases precipitated the pain attack. All patients positively responded to occipital nerve blocks with temperary relief of their pain, which was one of the mest important factors in patient selection for ONS.

The agr of the patients ranged between 22 to 63 years with a median age of 44 years. The patient population consisted of nine (64%) women and five (36%) men. The majority of patients presented with bilatized symptoms (64%, 9 of 14 patients). The remaining five (36%) patients were suffering from unilateral DN: three on the right and two on the left side.

In 8 of 14 (57%) patients, the possible underlying chilogical factors have been identified. Three patients underwent surgical interventions for Arnold-Chiari mallormation before the first episode of QN; those patients had history of crivical diskerbody with Jusien (one of whom also was diagnosed with fibromyalgia); one patient had previous neck trauma; and one patient was previously diagnosed with severe symptematic migraine, involving right side of the head. In the remaining six (43%) patients without any history of related or underlying pathology, QN was considered as idiopathic.

Medical therapy was unsuccessful or raused severe side effects that outworghed the therapeutic benefits in all patients. In addition, each patient routinely underwent neuropsychological evaluation to full out underlying depression, addiction, psychiatric disorder, or any other conditions known as predictors for an unsafistactory outcome. In eight (57%) patients, we performed diagnostic nerve blocks before the affirmulation procedure, which wore positive in all cases in bringing tempurary relief of pain after injection of the local anesthetic All other patients had similar blocks performed before referral to our institution.

The mean total follow-up of the series was 22 months, ranging from 5 to 32 months. The results of the treatment were assessed according to three criteria; 1) degree of pain est a visual analogue scale before surgery, during the high, and at first and last follow-up examinations after internalization of the stimulator; 2) consumption of analogueus before surgery and at consecutive follow-up examinations; and 3) the degree of patient satisfaction with pain relief.

Operative Technique: A Two-Stage Procedure

The first stage of the procedure (the trial) was performed under ould sectation and local amothesis to monitor patient's feedback and mesure the most optimal coverage of the painful areas by the stirmulation. After placing the patient on the

operating table in a prore position, a curved needle was inserted at the upper lateral end of the neek and advanced toward the midling of enancyestebral junction along the contour of the CI vertebral area under fluorescopic guidance, crossing over the anatomic course of the greater or lesson naripital nerves. When positioning at the needle was considered as satisfying, standard four-contact electrode (Quad PI-SCES, Meditronic Neutrological Inc., Minneapolis, MN; or Quatrode. Advanced Neuromodulation Systems Inc., Plano, TX) was advanced through the needle, and the tip of the electrode, containing four discrete contacts, was placed in close proximity of the greater or lesser occipital nerve. Correct position of the electrode(s) was verified by introoperative test stimulation of the awake patient and fluoroscopically (Figs.) and 2). Position was considered adequate if low to middle amplitude stimulation and small pulse width were enough to rover all painful acess. Once adequate coverage was achieved, the electracle was sutured in place with nonalworbable hylon sutures using two plastic anchors provided by the manufacturer to minimize the possibility of movement in addition to the suturing, the electrode was topaid to the skin and connected to the external stitutulation device. After final verification of the electrode position by fluoruscopy and lest stimulation, the patient was transferred to the tiscovery room and then discharged home the same day.

The polarity of electrode contacts and the stimulator settings were individually adjusted in every patient to optimally cover all painful areas. The parameters of stimulation varied widely from patient to patient and were as follows: the pulse width ranged from 90 to 80 ms, the frequency ranged from 90 to 90 Hz, and the amplitude ranged from 1.0 to 4.0 V. All patients went through a stimulation trial at home for 5 to 7 days where they were able to use the stimulator during their

normal daily activities. Tacy were allowed to adjust certain stimulation parameters, such as amplitude, frequency, and onlike width, within specified preset marginal values (usually within the range of ±15% from the optimal coverage values defined in the hospital) to adjust the stimulation coverage and intensity depending on their needs.

In tage of successful trial defined as more than 50% of pain reduction, the patient had the second part of surgical procedure performed tinder general anesthesia because of painful subculations wire transling and creation of the pusket for the implantable pulse generator (IIV.). The first incision was made along the schoalaricular area in a vertical direction. The soft tissues were dissected down to the fascia, and a small pocket was created above the fascia. The temporary electrode was recovered, and the standard four contact electrode was then positioned into the same anatomic location, which was confirmed by rough approximation of the baseline and subsequent fluorescopic images. Once the electrode was positioned in the right place, the needle was removed, and the electrode was anchored to facilitation provided plastic anchor.

Then, a subcutaneous pocket was created below the clavicle on the same side to accommodate the IPG. Extension cables were advanced through a subcutaneous tunnel, establishing connection between the electrode(s) and IPG. At the end, almusions were closed, cleaned, and covered with slente dressings, and the patient was transferred to the recovery room after waking up from general anosthesia and discharged home on the same or next day. Before discharge, the ONS system was turned on, and the settings of the stimulation were individually adjusted in every patient. All patients were given the upportunity to adjust certain settings of the stimulation at home based on their needs within preset values, which in must cases were similar to those used during the trial. At the first clinical follow up visit 1 to 2 weeks after the discharge,

patients reputied their overall satisfaction with the degree of pain relief and if it was necessary, the stimulator settings were once again adjusted to better fit each patient's individual needs.

RESULTS

All patients with permanently implanted QN5s term way in the outpatient clinic on regular basis for the follow up period averaging 22 months (5–32 mo). Overall, 23 occipital nerves were stimulated in 14 patients. Seventien (74%) trials in 10 (71.5%) patients were considered successful, and these patients proceeded to permanent internalization of the stimulator (Table 1). From these patients, the stimulation remained beneficial at least for 6 months after internalization in 100% (Table 2).

The intensity of the pain during the trial remained unchanged or only minimally improved in four (28.5%) patients. This happened despite intraoperative verification of the correct electrical placement confirmed by test stimulation. These patients did not proceed to internalization because their himelit from stimulation was insufficient to justify permanent implantation of the PNS system.

From those wise proceeded with internalization, at the time. of last follow up, two (20%) potients had their systems purfially or totally explanted because of complications. One patient, who continuously experienced proper relief by stimula-Fon, had part of the hardware removed because of intection. The second patient initially lost the effect of stimulation in early costoperative period because of migration of the electride and underwent an additional surgical pricedure for repositioning of the electrode. She regained reasonable atmoulation after repositioning and had satisfactory control of her pain for over a year. However, later on, she lost the effect of stimulation case again. In addition, the parient developed Eightness and spasms in the neck and right side of the budy. and respected for removal of the device. Another patient (10%) had her system explanted 21 months after the internalization of IPG because of complete improvement of pain and loss of need in stimulation.

The first two patients had figir pain return shortly after their systems were explanted. The pain was similar in distribution and intensity to prestimulation levels, and they required a combination of several analysis drugs for pain relief, whereas the last potions was completely pain free. The remaining seven (70%) patients with the implanted PNS system continued to have beneficial effects from chronic ONS ranging from 60 to 97% in pain rekef during their last follow-up. This resulted in a degreased amount of pain medications they have been taking for their pain control and the ability to return to normal daily activities and, for some, to gainful employment.

Overall, the beneficial effect of chronic ONS in our settlepersisted in more than half of the patients for whom procedure was considered and in 80% of these who significantly improved during the trial and proceeded with permanent device implantation (Pable 2). We had no intraoperative or

postoperative complications that would lead to any type of significant merbidity or mertality. Two (20%) systems had to be removed because of infection or loss of stimulation effect, and one (10%) system was removed because of significant improvement of pain and no need in stimulation. The remaining PNS systems continue to stay in plant and provide adequate pain relief to seven (70%) patients.

DISCUSSION

ON is one of several so-colled convicegenic headache syndrames with many euclogics and multiple treatment upuous (28). Pathological conditions most often implicated in the origin of ON are trauma, arthrific changes of the atlantosxial joint, cervical cord tumors, Chiari malformation, as well as ligamentous hypertrophy and sustained neck muscle contractions (11, 18, 30). A number of various treatments, both conservative and surgical, have been used to help propie suffering from ON, and the medical management, obviously, is the smost commonly used approach (5, 22). Chronic use of opioids and chemical neuromodulators, including anticpiscotic drugs and antidepresents in different combinations, alleviates paid in more than half of the patients with idiopathic ON (29). However, approximately one faird of all patients with ON. particularly those who have traumatic or arthritic etiology, become less sensitive to medications over time and require significant increase in oral drug intake, which may cause undesirable side effects, making it difficult to maintain the beneficial effect of the therapy. Recently, multiple is sections of bottuinum toxin inteneuk muscles, which todute muscle hyperactivity, have been proposed as a safe and semewhat of fertive method for treatment of ON (8, 19). Occipital nervo

thocks are even more effective and can provide immediate pain relief in almost every patient with ON, but the effect of breathrom texth injections and move blocks is temporary, and pain usually returns once the drug effect wears off (13, 38). However, nerve blocks are considered as a generally accepted standard bud for confirming the diagnosis of any peripheral neuralgia because the probability for the patient to have psychogenic pain syndrome increases significantly after failed nerve block trial (28). We used nerve blocks as an important tool to prove that the pain syndrome has its tools in the greater or lesser occupital nerve, and thus a successful nerve block was one of our prorequisites before considering the patient to be a candidate for stimulation trial.

Most destructive procedures, such as normaly is on gauglionectomy, are very effective in the treatment of different medically intractable pain syndromes (5, 9, 20, 31). However, the use of this modality for treatment of intractable ON is very controversial. Once an anatomic structure is destroyed, it cannot so usually recovered, and with any destructive procedure, there is always a risk of development of painful norrows or causalgia, conditions that may be even harder to control than the original neuropathic pain. As opposed to the distructive precedures, neuromodulation with chronic nervo stimulation is completely reversible. If the patient decides not to use this treatment modality in the future, the system can be easily harned off or even removed without any consequences, and the patient will stand exactly at the some point where he was before implantation, open to any other treatment option. The ONS is based on the same principles as the more commonly used technique of spinal condictionalation (39).

Although chrosic periphera normasticulation was described almost 40 years ago for the treatment of normastic

¹⁹ Detinoid based on obtemilia overall rating of pain to 90 al.

pain syndromes (33), it seems that there are many variables that may contribute to the surveys of this treatment modality. Ober of the difficulties in delivering stimulation to the area of they and back of the head has been the issue of electrode. placement. The anatomic environment has to make it possible. to place the electrode in the right incation. Scar formation from previous surgical interventions or trauma could prevent the surgenn from advassing the electrode to the desired location. In addition, the stimulated nerve must be intact so the stimulation signal passes through the nerve and is not blocked by deafferentation or discontinuity along the nerve trunk. This is why performing the initial step of electrode insertion under local enestrosia may be important because it assures adequate positive feedback from the patient during the procedure and helps to maximally cover all painful areas with stimulation. Intraoperative test stimulation and direct hexback from the patient allowed us to get adequate pareathesis coverage in all patients from our series. Mureuver, because the placement of the electrode for trial atimulation by itself was not a very complicated surgical procedure and this not require keeping the patient under general anesthesia, it has been performed on an outpatient basis, which in turn minimized the hospital stay time for these patients and, consciprintly, reduced the overall cost of the friatment.

We found that an important prerequisite for successful treatment of ON with peripheral neurostimulation is careful patient selection. Similar to spinal condistimulation, certain neuropsychological and social findings condice very accurate in predicting an undestrable outcome. For example, presence of depression, drug addition, unrealistic expectations, a long listury of different procedures and approaches in the past, or social exonomical benefits may all be reasons for inadequate pain relief in such patients. In addition, a 1-week (5-7 d) trial period is usually given to every patient before internalization of the permanent device, which makes it possible for the patient to extensively test the stimulation and adjust the settings to his daily meets, assuring that stimulation provides adequate pain relief and proves beneficial for long-term use.

Another important prorequisite for considering any patient with ON for sumulation trial should be alleviation of the pain. with occipital nerve block. The effect of any nerve block is always transitory. However, it is interesting that after the occipital nerve block, the pain may disstically reduce in other areas of the head as well that an not correlated anatomically to anosthetized areas (28). This phonomonum can explain the beneficial effect of chronic ONS in migraine patients. The stimulation of greater occipital nerve in these patients relieves. the pain not only in the compital region but also in the fromtotemporal area (23). It has been shown in an experimental animal model that the attenuistion of the greater occipital nerve inarcases metabolic activity in both typically regularly regions of the spinal cord and in the trigemutal nucleus caudolig through the so-called trigerninecerviral complex, which consists of functional connections between meningeal inputs and greater occipital nerve affectors (2, 10). This functional coupling between neciceptive meningeal afferents and convical afferents in the greater excipital nerve occurs at the secondorder neuron level in the upper spinal road (1, 27). Another position emission tomographic study of eight patients with migraine who have had a marked response to chronic excipital stimulation showed significant changes in regional combinal blood flow during the stimulation in the anterior cingulate cortex, concus, and left pulvinar nucleus, which directly correlated with parasthesia scores and inversely correlated with pain scores (23).

Although most of these studies were performed at patients with chronic intgrame or in experimental headache arumal models, the proposed mechanism may be also responsible for pain relief in patients with ON and secondary generalized headaches. The small size of our series does not allow us to confirm or dispose this hypothesis.

All fear patients from our series who did not proceed with internalization reported insufficient pain relief during the trial period, although in all cases, the correct placement of the electrode has been confirmed with intraopurative patient feedback and adequate coverage of painful areas by stimulation. Moreover, we did not find any particular difference between responders and nonresponders related to parameters of stimulation meal, and diagnostic nerve blocks resulted in adequate temporary alteriation of the pain in all four patients. Thus, our experience shows that the stimulation trial remains an important step for apprepriate patient soluction because the patients who failed the trial did not differ from those who passed in even with thorough physiological testing and more psychological evaluation.

Because we had a relatively small series (only 14 subjects) and a very large variation between patients in regard to the etiology of their ON, we were not able to find any particular correlation between criology of ON and the outcome of stimulation. A long-term prespective clinical study with a bigger series of patients is needed to define such a correlation.

In our current series at 14 patients, 10 successfully passed the trial and proceeded with inhumalization of the PNS system, from those, only two (20%) patients had hardware related complications that required their systems to be explanted after at least 12 months of continuous use, which corresponds to an 30% overall success rate of long term ONS.

One (10%) patient requestixt her system to be removed 21 munchs after the implantation because of significant improvement of pain and no need for stimulation for over 6 months (Table 2). She was completely pain free at the time of her last follow-up (3 mo after the system was explanted). The remaining seven PNS systems continue to provide satisfying paintrate in seven (70%) patients.

Thus, we believe that PNS may be an effective and very premising method for long-term treatment of intractable ON. With the increasing number of procedures, the surgical technique will further improve, which in form will lower the overall rate of minor complications we encountered. In addition, because neuromodulation systems have become more flexible currently, the effects of a minor shifting of the electrode or increase in electrical impedance caused by son for

mation, for example, may be easily corrected by changing the active contacts on the electrical correct. The remote control width and voltage of the electrical correct. The remote control allows one to turn the stimulator on and off, increase or discrease certain settings within given ranges, opening for patients the possibility to adjust stimulator settings to their daily activities, thus providing botter pain control over time, which in turn results in improvement or psychological well-being in most patients.

CONCLUSION

The approach, technique, and results described in this paper demonstrate that thronic peripheral neurostimulation may be a sale and effective treatment for intractable ON and that the long term benefit derived from chronic ONS appears to be dutable. Although this is limited experience from a single center and needs to be expanded further, our results suggest that chronic peripheral neuromodulation is a promising surgical treatment modulity for patients with medically intractable ON.

COMMENTS

This study of cleven patients with a mean follow-up of almost two years reamines for officery of occipital neurostimulation in the treatment of occipital neurostig. Out of the initial eleven patients entered into the study, three failed to obtain measurable benefit even early in their hearment and were not fully implanted. In addition, three patients had their devices explanted because of other loss of benefit or infection. Of the remaining six patients, the appear to be either earn free ensign fauntly improved on last techneup. Therefore, tive or the eleven patients studied appear to be injoying significant relief of their pain an everyge of a most two years following stimulation. Despite the small number of patients in this study. Been tead to see promising. The technique described is exceptionally easy to perfectly, and appears to hold significant promise in a very refractory group of patients.

Although this study supports the use of neurostimulation for the treatment of occipitor neural gravit is irroted by the rather losse way to which it was conducted. For example, the only official for occupital memoratimulation in this group were based resirdy on the results of a diagnostic block, and the patients are otherwise a rather diverse group. with a number of other pain conditions. Significant "cuise" is thereforgrintendered into the system which may well affect the outcome of econ a small stooy, to addition, the corrorne measures abbeen a bit. larse. The authors state that pain relief ranges from 60-80% in the five supressful pair only, and that these patients enjoyed a reduction in pain. medicine intake as well as a return to normal activation and sorak. If fortunately, since this is a petrospective study, one cannot gain insight into mere objective measures of success (functional scales). measures of sualgeric tree, etc.). Stilly describ these limitations, this study does support the residua of other angolobal woods of this technique and should stimulate a more rigorously controlled, prospective study.

There are corrently a growing morber of neurosurgrous and anotheriologists using occipital neurosticulation in the treatment of occipital pain syndromes, based upon the description of the technique by Welner (1). The therature documenting occipital stimulation is still largely aneolotal inverse (e.g., 2). The current study by Sovin et al. is therefore a violotic addition to the Eferature Although it is still a retraspective analysis of a relatively small group of patients (and therefore considered Class III (large), this study does document the results of onlipital neurostimulation in a more explicit evay than has been done proviously. I am hopeful that the Slavin will tellow up this pilot data with a prespective trial that will help delineate the uses and limitations of this technique.

Oren Sagher Ank Arbot, Mädigen In this paper, the authors present a retrospective case series of subcutaneous electrical stimulation for obticital nerve pain. A total of 14 patients, all of whom responded to large arcsthetic blockade of the occipital nerves, were facilitied in the 30-by, both undersons percutaneous placement of a total electrode. A total of 10 patients experienced greater than 50% relief of pain for five to seven days and proceeded to implantation of the pulse generator. All of these patients experienced relief for six months after implantation, and eight experienced angoing 50% improvement of symptoms. Three devices of the 10 total were removed; one due to complete resolution of pain, one due to loss of herefit, and another due to infection.

This case series provides some insight into the potential benefits of peripheral stirrulation for ordipital nerve pair. The patients are constitutly selected, with each having resolution of pain with local ansethic is nerve blockade. It is interesting to note that although just over half of the patients with diagnostic nerve blockade went on to long term benefit from electrical stimulation, all but one patient with a successful stimulation trial benefited from their one patient with a successful stimulation trial benefited from their one patient with a successful stimulation trial benefited from their operation. These results are enoughly, particularly as nerve stimulation likely passes lower rack to patients from traditional shielier approaches. Remaining questions involve the relationship of point inlegg to colonital benefit and the factors that predict and differentiate meatined responses from text ment failures. To answer these important questions a larger patient population and prospective study is required.

Necromodulation Prerspies for chronic pain are increasingly growing and new indications emerging Perisps, pain syndromes involving the head and face are emerging to treat challenging to test. Obelighal remodiple is a common pain condition. A significant moder of pathonal with enopital neurality have intectable pain despites optimal medication, blocks and other therapies. Surgical therapies have traditionally consisted of resection and estimating procedures. Recently, neurostimulation has been utilized for treating compital actuality.

The authors report a series of 11 patients with intrartable compital according who underwent trial of occipital nerve stimulation. All patients underwent murapsychological decrance and successful occipital nerve blocks. The authors used a percutaneous approach with implantation of quascripular series viscturdes and authorseative venification of paresthesias covering the occipital region of pair. All patients underwent a stimulation test-trial lasting tive to a contrary. Eight of eleven patients undergoing the initial trial received a permanent implant. Eve patients had significant long-term pain relief (ranging from 60-80%) with an everage of 22 month follow-up.

The authors provide an important contribution to the field of neuremodulation and chaosic paid neurogary. They have shown good outcomes using a minimally invasive approach and long term followup. The results from this series should encourage further controlled studies with larger series of patients.
